Research involving nonhuman primates (NHPs) has played a vital role in many of the medical and scientific advances of the past century. NHPs are used because of their similarity to humans in physiology, neuroanatomy, reproduction, development, cognition, and social complexity—yet it is these very similarities that make the use of NHPs in biomedical research a considered decision. As primate researchers, we feel an obligation and responsibility to present the facts concerning why primates are used in various areas of biomedical research. Recent decisions in the United States, including the phasing out of chimpanzees in research by the National Institutes of Health and the pending closure of the New England Primate Research Center, illustrate to us the critical importance of conveying why continued research with primates is needed. Here, we review key areas in biomedicine where primate models have been, and continue to be, essential for advancing fundamental knowledge in biomedical and biological research. *Am. J. Primatol.* © 2014 Wiley Periodicals, Inc.

Key words: animal models; translational research; nonhuman primates

Deep brain stimulation, Parkinson's disease, the use of incubators for premature infants, treatments for asthma, development of drugs to control transplant rejection ... these are some of the major medical advances in recent years that have depended on the use of nonhuman primates in biomedical research and testing.

Research involving nonhuman primates (NHPs) has played a vital role in many of the medical and scientific advances of the past century. NHPs are used because of their similarity to humans in physiology, neuroanatomy, reproduction, development, cognition, and social complexity—yet it is these very similarities that make the use of NHPs in biomedical research a considered decision. As primate researchers, we feel an obligation and respon-

sibility to present the facts concerning why primates are used in various areas of biomedical research. why continued research with primates is needed. Here we review key areas in biomedicine where primate models have been, and continue to be, essential for advancing fundamental knowledge in biomedical and biological research.

PHYLOGENETIC CONTEXT

The vast majority of biomedical research utilizes rodent models. U.S. government statistics indicate that approximately 90% of the animals used in research are mice, rats and other rodents. NHPs account for 0.28% of all laboratory animals used in research [Government Statistics from 2010]. The appropriateness of various animal models depends upon not only the species but also the ways in which the models are used. In particular, the model needs to parallel not only the clinical and biological features but also the behavioral repertoires of interest. While rodents are, and will continue to be, extremely valuable models for biomedical research, rodents do not always accurately model human behavioral and biological response [Seok et al., 2013]. The evolutionary distance between rodents and humans [human-mouse-rat ancestor ~87 mya; [Springer et al., 2003] presents significant differences in biological and behavioral function that may limit the immediate translational value of findings.

The close phylogenetic relationship of NHPs to humans makes them excellent models for particular biological phenomena. The physiological similarity between humans and NHPs means there is greater validity of the data obtained from primate models than other animal models (e.g., reproduction and pregnancy, cognition, and cognitive aging). This physiological similarity also means that one can address questions using NHP models that cannot be addressed using other species (e.g., models of AIDS, lung disorders, and drug metabolism). Old World monkeys (rhesus macaques, baboons, vervet monkeys) and New World monkeys (marmosets, squirrel monkeys, titi monkeys, capuchin monkeys) are used frequently; prosimians and Great Apes (chimpanzees) are also used, though less frequently (see Fig. 1). As the NIH recently decided to phase out the use of chimpanzees in most areas of research, chimpanzee models for furthering our understanding in key areas such as autism and Hepatitis C will no longer be available. In cases where NHPs are used, species selection is carefully considered, taking into account behavioral, biological, animal welfare, and practical considerations [Group, 2002; Smith et al., 2001, 2013].

ETHICAL CONSIDERATIONS IN THE USE OF PRIMATES IN BIOMEDICAL RESEARCH

The ability of all animals to feel pain and experience stress means that researchers have a

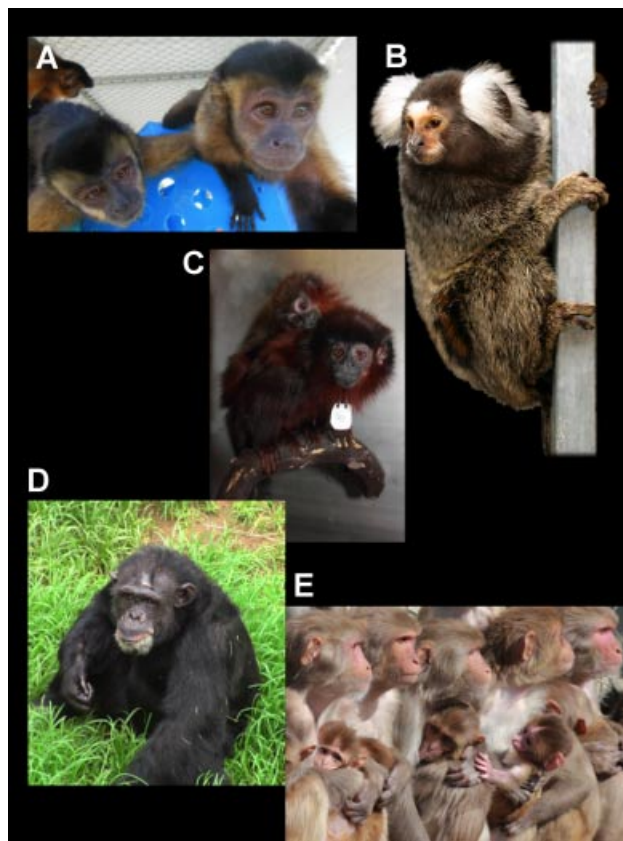

Fig. 1. Primate species frequently used in biomedical and behavioral research include (A) capuchin monkeys (*Cebus apella*; photo: Kimberley A. Phillips); (B) common marmoset (*Callithrix jacchus*; photo: Biomedical Primate Research Center); (C) titi monkeys (*Callicebus cupreus*; photo: Kathy West); (D) chimpanzee (*Pan troglodytes*; photo: William D. Hopkins); and (E) rhesus macaques (*Macaca mulatta*; photo: Kathy West).

moral obligation to conduct research in a manner that reduces negative effects and does not unnecessarily cause stress or suffering. The significant cognitive capacity and complex social behavior of NHPs raises additional issues concerning the rationale and justification for their use in biomedical research. The fundamental ethical dilemma concerning the use of primates in biomedical research is whether we can be morally justified in conducting research that benefits humans but which may cause NHPs pain, distress, and/or suffering. The core issues reflect whether NHPs count in our moral considerations, and whether they have moral standing. A being has moral standing if its interests must be given consideration in the deliberations of a moral agent. If an individual has moral standing, then the individual has a valid interest in the moral norm, and they count in a moral sense. Thus, having moral standing restricts the permissible range of conduct toward these beings. Properties that are frequently taken into account when considering questions of moral standing include being sentient, rational, and a

self-conscious agent. While NHPs exhibit aspects of rationality and agency, these do not reach the level seen in humans. Sentience is what many regard as the primary trait that gives NHPs moral standing [Bentham, 1907 [1823]; Morris, 2011]. Another feature of the debate concerning the moral standing of NHPs is whether they are direct or indirect moral objects. If NHPs are direct moral objects, then we have direct duties *to* them. If NHPs are indirect moral objects, then we have duties *regarding* them but not duties *to* them [Aquinas, 1955–1957; Kant, 1996 [1797]; Morris, 2011]. A consensus as to the moral standing of NHPs, or whether a distinction between direct and indirect moral objects is warranted, cannot be reached even among philosophers.

However, the growing recognition by researchers, veterinarians and other biomedical professionals that ethical issues such as these are important and relevant to primate research has led to specific changes in the way such research is conducted and regulated. Greater attention is now paid by the various participants in the research enterprise (scientists, veterinarians, and administrators) to the responsibilities that someone is accepting when they choose to engage in research using NHP. This has been an important stimulus leading to concrete, practical, and enforceable changes in the procedures and standards required, including legal restrictions and government policies that are tied to research funding. Fifty years ago, there was little formal oversight on the use of animals in research. While most research was done with appropriate concern for the health and welfare of the animal subjects, this was not always the case and a series of regulations and laws were thus enacted to ensure proper methods and housing conditions. Today, all research using NHPs (and indeed all research on vertebrates) in the United States must adhere to an extensive series of laws and/or regulations. No academic or commercial research using NHPs can be performed unless: (a) the researchers have appropriate training in the use of animals, (b) there is independent oversight on the procedures to be used, (c) the researchers have satisfactorily justified in writing the species to be used, the number of animals to be used and the scientific significance of the data to be generated and (d) there is evidence that the work does not unnecessarily duplicate prior research. One of the changes that most clearly reflects the changing attitudes, and also has immediate daily impact on the primates maintained in research colonies, is a series of regulations regarding the psychological well-being of the animals. There are now explicit and enforceable rules that go beyond requiring adequate food, housing and veterinary care to address the cognitive and psychological complexity of NHPs, providing assurance that these issues are given substantive attention. The rules apply whether or not any particular animal is actually being used in a

research project [Office of Laboratory Animal Welfare, 2013]. This reflects the broad acceptance of the idea that researchers and veterinarians have a responsibility to attend to the psychological needs of the animals as well as nutritional and environmental needs.

In all research institutions, investigators must convince a set of independent experts that the work they propose to do is justified and will be performed appropriately. These committees (Institutional Animal Care and Use Committees), which are mandated by Federal law, function separately from the research team and the funding agencies and have the right and obligation to restrict or stop any primate research that the committee considers unnecessary, inappropriately designed or inadequately justified given the effects on the study subjects. These committees must include non-scientists and representatives of the community (lay members), to ensure that community standards for ethics are followed.

Most (>95%) behavioral and biomedical research with nonhuman primates either does not involve pain, or the pain is alleviated with analgesic or anesthetic drugs [Animal and Plant Health Inspection Service, 2010]. Pain causes stress, and researchers understand that stressed animals present different biological responses, which may affect the results of the study. Animal suffering and use are minimized in line with the 3Rs principle of Russell and Burch [1959]: replacement, reduction, and refinement. Researchers must specifically address the 3Rs before any research project with NHPs is approved, and guidance is available to assist researchers in implementing the 3Rs [Refinement, 2009]. Furthermore, provisions under the Animal Welfare Act require needs specific to NHPs be addressed. As such, efforts are made to enhance psychological well-being through social housing, addressing the specific social and development needs of infants and aged individuals, and providing environmental enrichment. The major professional societies whose members use NHPs in research—Association of Primate Veterinarians, American Society of Primatologists, and the Society for Neuroscience—endorse policies and regulations that provide for the enhancement of NHP psychological well-being. At institutions that utilize NHPs in research, considerable ongoing research and evaluation occurs to further improve the welfare of captive NHPs.

The requirements of the Animal Welfare Act (AWA) are set forth under the Regulations and Standards in the Code of Federal Regulations (CFR). These requirements are found in Title 9 CFR, Chapter 1, Subchapter A—Animal Welfare, Parts 1, 2, and 3. The requirement for the psychological well-being of primates is set forth under section 13(a)(2)(B) of the AWA (7 USC, 2143). The standards for environmental enhancement to promote psychological well-being in primates are set forth under 9 CFR,

Chapter 1, Subchapter A—Animal Welfare, Part 3, Section 3.81.

Some have argued that human rather than nonhuman primates are the more appropriate, and ethically preferable, subjects for biomedical research (e.g., Quigley, 2007). The logic behind this is that despite the similarities between humans and NHPs, small but significant biological differences exist. Therefore, conclusive results cannot be obtained from NHP models, and so the ethically preferable choice would be to experiment on a limited number of humans. This position may seem intuitive on some level. However, we should be reminded that it is essential for the protection of humans that prior research be conducted on animals. The Nuremberg Code, written as a result of the Nuremberg Trial at the end of World War II, defines a set of research ethics principles for human experimentation and states animal studies must precede research on humans. The experiment should be so designed and based on the results of animal experimentation and knowledge of the natural history of the disease or other problem under study, that the anticipated results will justify the performance of the experiment [Permissible Medical Experiments, 1949]. The

use of sentient NHPs rather than other animal models certainly requires greater ethical consideration of whether a specific experiment is justified. Justification includes the appropriateness of the primate model (which we illustrate below for specific research areas; see Table I) as well as potential costs and benefits of the research. As long as we believe that a human life is more valuable than a fish, fly, mouse, or primate, some experiments will be performed on animals before exposing humans to risk. And in some cases, the best animal model will be a NHP.

The scientific summaries provided below for several key areas (though not exhaustive) illustrate that there is a wide range of significant and valuable biomedical information that can only be obtained by using NHPs in research. Thus, while we recognize the responsibility researchers take on themselves when they engage in research using primates, we also recognize and document that NHP research has generated results that have saved many human lives and reduced suffering in many more. The summaries focus almost exclusively on studies performed in captivity; we recognize, however, that important information in some of these topical areas has been

TABLE I. The Major Advantages of Primate Models for the Areas of Biomedical Research Covered in This Review

Area of research	Advantages of primate models
Atherosclerosis	Similarities in etiology and characteristics of arterial pathology, including reproductive and central nervous system characteristics that promote or protect against atherosclerosis
Behavior	Similarities in social and environmental complexity allows for ethologically relevant inputs to behavioral paradigms for social cognition and psychopathology
Cognition and language	The relatively large brain size in NHPs compared to other mammals makes them invaluable for testing evolutionary models of human cognition
Cognitive aging	Greater similarities with humans in brain functional specialization associated with cognitive aging, such as the nuclear organization, projection pathways and innervation patterns of the hippocampus
Developmental programming	NHPs (but not rodents) share with the humans an interdependence of the fetal and maternal hypothalamo-pituitary-adrenal axis and their interactions with the placenta
Genetics	Share with humans fundamental genetic processes relevant to specific diseases (that other mammalian species lack), such as KLK3, the gene that produces prostate-specific antigen
HIV/AIDS	The only animal model for HIV/AIDS; provides the chance to control variables and conditions of infection
Immunology	Most similar to humans in regards to the developmental maturation of the immune system
Neuroscience	NHP brains closely resemble human brains in several ways, including encephalization, the number and density of cortical neurons, a large prefrontal cortex, and greater myelination; additionally, some functional areas of the NHP and human brain do not exist in the rat
Pharmacology	Allow for the ability to track changes in the brain and sensitivity to drugs over time, and study individual differences in these effects
Reproduction	Share with humans key characteristics of endocrine regulation of reproductive physiology not seen in other mammals that include fundamental differences in hypothalamic feedback, ovarian function, the physiology of the uterus and vagina, the establishment and control of pregnancy and menopause
Respiratory diseases	Reflect key features of human lung architecture and immunity

obtained from field studies as well [Emery Thompson, 2013; Fedurek & Slocombe, 2011; Tung et al., 2010].

ATHEROSCLEROSIS

Atherosclerosis of the coronary arteries and its complications are the principal pathological processes that result in coronary heart disease (CHD). Macaques (*Macaca spp.*) have been a well-established model of diet-induced coronary artery atherosclerosis (CAA) for several decades [Jokinen et al., 1985; Wissler & Vesselinovitch, 1977]. It is likely that the utility of this model is due to their close phylogenetic relationship to human beings, which has resulted in similarities in etiology and characteristics of arterial pathology.

For example, macaques develop arterial lesions similar to those seen in human beings. Dietary manipulation results in hyperlipidemia, which resembles that found in humans. Also, these species are a convenient size for diagnostic and therapeutic studies. By comparison, rats are generally resistant to atherosclerosis. The lesions they do develop are unlike those of human beings, and severe experimental conditions may be required to produce them. Atherogenic diets may result in high mortality in mice, and produce lesions that are unlike those of humans. However, the relative ease of genetic manipulation and the relatively short time frame for atherogenesis makes them useful for investigation of gene effects [Getz & Reardon, 2012]. Pigs faithfully recapitulate human atherosclerosis but their large body size makes them difficult and expensive to handle and maintain. Atherosclerosis lesions are easily induced by diet in rabbits but the resulting lesions, and cholesterol metabolism in general, are dissimilar to human beings; the latter may result in extreme hypercholesterolemia and lipid storage in organs [Jokinen et al., 1985].

Perhaps the most valuable aspect of macaque models of atherosclerosis is that they provide information on important etiologic factors that promote or protect against atherosclerosis; these factors involve reproductive and central nervous system (CNS) characteristics that are unique to primates. For example, Old World Monkeys and Apes have menstrual cycles similar to those of women. Adult cynomolgus monkeys (*Macaca fascicularis*) are a well-characterized animal model of sex differences in susceptibility to diet-induced atherogenesis. While females are generally protected compared to males, ovariectomy results in extensive CAA. If estrogen therapy is begun right after ovariectomy, females are protected from CAA [Adams et al., 1990; Clarkson & Mehaffey, 2009]. Likewise, the results of large observational studies such as the Nurse's Health Study suggest that hormone therapy initiated around the time of menopause reduces the risk for a major

coronary event by about 50% [Grodstein et al., 2000; Stampfer et al., 1985]. However, in monkeys, if estrogen therapy is not initiated until 2 years after ovariectomy (approximately equivalent to six human years), there is no beneficial effect on atherosclerotic plaque size [Clarkson & Mehaffey, 2009; Register et al., 1998; Williams et al., 1995]. This observation essentially predicted the outcomes of both the Heart and Estrogen/Progestin Replacement Study (HERS) and the Women's Health Initiative (WHI), in which delayed initiation of estrogen therapy for about 15 years after menopause was associated with no overall cardiovascular benefit [Hulley et al., 1998; Rossouw et al., 2002].

Likewise, intact cynomolgus monkeys with poor ovarian function develop extensive CAA like that of ovariectomized females [Adams et al., 1985]. This is not surprising, because females with low progesterone concentrations in the luteal phase also have low estradiol concentrations in the follicular phase, that is, they are estrogen-deficient. The effects of premenopausal ovarian dysfunction on CHD risk in women are difficult to evaluate, because long-term characterization of hormone levels over the menstrual cycle is problematic. However, women with a history of irregular menses are at increased risk for CHD [Solomon et al., 2002]. Thus, ovarian function, and in particular estradiol, confers protection from CHD in women and CAA in female cynomolgus macaques.

Psychosocial stress is a well-recognized CHD risk factor that doubles the risk of myocardial infarction in human beings with traditional risk factors [Steptoe & Kivimäki, 2012]. Macaques depend on their social relationships, and psychosocial factors also affect their health. The stress of low social status results in a twofold increase in CAA in females due, at least in part, to the social suppression of ovarian function [Kaplan, 2008; Kaplan et al., 2009].

In female cynomolgus monkeys consuming a Western-like diet, 60% of subordinates and 10% of dominants develop depressive-like behavior [Willard & Shively, 2012]. This social-stress associated depressive behavior is accompanied by perturbations in the CNS including small hippocampi and decreased serotonin 1a receptor binding affinity, autonomic perturbations manifested as high 24 hr heart rates, perturbed hypothalamic-pituitary-adrenal function, poor ovarian function, dyslipidemia, and low activity levels. These characteristics are reminiscent of major depressive disorder in human beings and most have not been reported in other animal models of depression [Shively & Willard, 2012]. Furthermore, cortical areas known to be critically involved in depression in human beings are not elaborated or differentiated in nonprimate species [Hamilton et al., 2012]. In human beings, depression and CHD are highly comorbid, and when depression is present the prognosis for CHD is greatly worsened [Leung et al., 2012]. Adult female

cynomolgus monkeys that display depressive behavior develop four times more CAA than their nondepressed counterparts, faithfully recapitulating the depression—CHD comorbidity in human beings [Shively et al., 2009]. Thus, this species may be used as an animal model in which to study the comorbidity of depression and CHD.

In summary, macaque models of CAA are unique in that they recapitulate the pathobiology of CAA, and the primate-specific etiology of reproductive and CNS effects on CAA/CHD risk in human beings.

BEHAVIOR

In health-related research, behavior is most often used as an output measure for models of psychopathology, or as treatment responses to psychoactive drugs. In this context, there are a number of behaviors that are both upwardly and downwardly translatable—that is, quantifiable in rodents, NHPs, and humans—as well as some behavioral paradigms that are uniquely available in NHPs and humans.

Social deficits are a feature of many mental health disorders, including autism, schizophrenia and social anxiety [APA, 2013; Baird et al., 2003]. The availability of NHP models with widely differing social systems and behavior makes them suitable for a number of different questions. The most common biomedical model, the rhesus monkey (*Macaca mulatta*), lives in large multi-male/multi-female groups with strong dominance hierarchies [Capitaino et al., 2006]. As Old World monkeys, they are more closely related evolutionarily to humans than any group except the apes and display high levels of social intelligence [Thierry et al., 2004], as well as personality dimensions remarkably similar to those of humans [Capitaino, 1999]. They have proven particularly useful in studies of faces, both of facial expression [Parr et al., 2013], and facial recognition, due to their ability to recognize individuals from photos or video [Habbershon et al., 2013; Silwa et al., 2011]. In particular, new and sophisticated eye-tracking techniques [Machado & Nelson, 2011], very similar to those used in humans, allow a measure of social attention that is not available in rodents. Abnormal eye gaze is commonly found in studies of humans with autism spectrum disorders [Guastella et al., 2008] and schizophrenia [Morris et al., 2009]. Visual tracking of eye gaze in NHPs has been designated as one of two priority behavioral paradigms for social cognition in animal models of schizophrenia by the CNTRICS initiative [Millan & Bales, 2013].

Other primate taxa, while not as closely related to humans, provide opportunities for alternative translational models of social behavior. Socially monogamous New World monkey species, which form long-term, heterosexual social bonds such as titi monkeys (*Callicebus spp.*) [Fernandez-Duque

et al., 1997; Mason & Mendoza, 1998; Mendoza & Mason, 1997] and owl monkeys (*Aotus spp.*) [Fernandez-Duque & Huck, 2013; Fuentes, 1999], allow researchers to examine the basic neurobiology and permit pharmacological manipulation of social behaviors such as male parenting, food-sharing, and adult male social bonds. Marmosets and tamarins (family Callitrichidae), while not displaying traditional social monogamy [Fuentes, 1999] display other social behaviors shared with humans, such as alloparenting behavior [Bales et al., 2000; Tardif et al., 1992]. Compared to larger non-human primate species, these New World monkey species are smaller in size, easier to handle, and do not carry zoonotic diseases such as Herpes B virus [Tardif et al., 2006].

Many non-social aspects of behavior can be modeled in rodents, NHPs, and humans, and thus provide continuity of interpretation across species and studies. Startle responses, and the ability to inhibit these responses (prepulse inhibition, or PPI) based on an acoustic prepulse, are commonly used as measures of sensorimotor gating [Millan et al., 2012], and reveals multimodal deficits in schizophrenia [Thoma et al., 2007]. Startle amplitude and PPI are modeled in rodents using startle boxes with either acoustic or tactile (air-puff) stimuli, and in NHPs and humans using the effects of acoustic or air-puff stimuli on whole body startle or eye blink [Davis et al., 2008]. Despite the comparability of behavioral startle paradigms, the neural substrates differ between rodents and primates, being independent of the amygdala in primates but not in rodents [Antoniadis et al., 2007]. Other, simple non-social behaviors that can be compared across species might include locomotion and stereotypical behaviors [Novak et al., 2013].

In comparison to rodent models such as rats (*Rattus rattus*), mice (*Mus musculus*), and prairie voles (*Microtus ochrogaster*), all primate models display a more extended, human-like period of development [Walters, 1987]. In many species, offspring often remain in the natal group well past the age of sexual maturity. This can be particularly important in studying behavioral aspects of juvenile and adolescent periods.

In addition to mental health research, primate social behavior has been the basis for a new group of biologically inspired computational models [Bales & Kitzmann, 2011; Zhang et al., 2009]. Scent-marking behavior, in particular, has been used as a model for mobile sensor communication in which delayed information can be relayed [Xiao et al., 2011]. Cooperation between animals, including primates, has also been used in a number of engineering applications [Liang & Xiao, 2012]. Social hierarchies are of special interest to engineering [Markham, 2011], and primate social hierarchies have been previously modeled using agent-based modeling, a technique

frequently utilized in engineering and computing applications [Bryson, 2007].

COGNITION AND LANGUAGE

The use of nonhuman primates has been central to elucidating principles underlying learning and memory as well as more advanced cognitive function. Further to this point, Harlow developed the Wisconsin General Testing Apparatus as a direct consequence of his early effort to studying discrimination learning and memory in primates [Harlow, 1949]. Indeed, primate behavior and cognition has been a central focus in biology and particularly in psychology, almost from their conceptions as scientific disciplines. The early works on learning theory by Thorndike, Watson, and Skinner were dominated by studies in rats and other more distantly related species with little recognition or acknowledgment for potential species differences in cognition. Yet, even early on, many questioned strictly operant explanations for cognitive phenomena in primates, notably the infamous studies describing “insight” learning by Kohler [1925]. What distinguishes cognition from traditional views of animal learning is the role that reinforcement history has on the behavioral performance. In this realm, studies from nonhuman primates have been particularly significant. For instance, Gallup reported that when chimpanzees were confronted with mirrors, they treated the image as a reflection of themselves rather than another conspecific chimpanzee [Gallup, 1970]. Interestingly, subsequent studies have shown that other apes show self-recognition but this ability appears absent in other more distantly related primates [Povinelli, 1987; Povinelli et al., 1997]. The evidence of self-recognition in apes compared to other primates has been the foundation for neurobiological studies that aim to identify uniquely ape and human characteristics of the brain, which may explain these abilities. One such neurobiological landmark is Von Economo neurons (VENs), which are found in abundance in the anterior cingulate and insular cortex of humans and apes but are rather sparsely found in the regions in most Old and New World monkeys [Allman et al., 2011]. Whether VENs play a role in self-recognition or self-awareness is unclear but the critical point is that the only valid model for demonstrating their potential role in these aspects of cognition is primates.

The value of primates for testing evolutionary models of human cognition is not restricted to self-recognition. It is now well recognized that primates are much better animal models of human cognition in a variety of domains including inhibitory control and delay of gratification [Rosati et al., 2007], meta-cognition [Beran et al., 2013], cognitive representation of motor actions [Christel, 1994; Frey and

Povinelli, 2012, #8393], planning [Menzel & Menzel, 2007], and lateralization of structure and function [Hopkins, 2013]. All of these abilities are likely attributable to the relatively large brain size in primates compared to other mammals.

Perhaps no other domain of cognitive research has been more influential and recognized in the public domain as the studies of the linguistic capacities of apes. Initial attempts to teach apes to speak failed miserably, but starting in the 1960s, efforts to teach apes language using alternative communication systems involving sign language, plastic chips, or visual graphic symbols were all highly successful in demonstrating a variety of basic language skills including symbolization, basic semantic representation [Savage-Rumbaugh et al., 1993], categorical representation, spoken English comprehension [Savage-Rumbaugh & Lewin, 1994], and rudimentary grammar [Greenfield & Savage-Rumbaugh, 1990]. From a theoretical standpoint, the ape-language research, as well as studies on vocal and gestural communication in monkeys and apes [Call & Tomasello, 2007], has no doubt helped in defining what characteristics of language are unique to humans and those that are shared. For instance, apes and humans both seem capable of learning and using symbolic communication systems, it has become increasingly evident that only humans seem to combine these symbols into multiword utterances in order to create new meanings. Pragmatically, the ape language work has been instrumental in the development of technology and methods used to assist disabled children in learning to communicate [Rumbaugh, 1977].

COGNITIVE AGING

With advancing age, cognitive functions begin to decline in both humans and nonhumans. The specific cognitive domains that become altered with age and the brain mechanisms that underlie these declines have been the subject of investigation for many decades. NHPs are critical animal models that have provided valuable and unique contributions to our understanding of cognitive aging and to our search for possible treatments for cognitive decline with age.

NHPs are closest to humans phylogenetically [Finch & Austad, 2012; Kumar & Hedges, 1998] and the structure and function of human and NHP brains are very similar (see also Neuroscience section below). The rhesus monkey hippocampus more closely resembles the human hippocampus in terms of nuclear organization, projection pathways, and innervation patterns than does the rodent hippocampus [Amaral & Lavenex, 2007], and NHP and human brains are especially similar in cortical development and organization [Hutchison & Everling, 2012; Petrides et al., 2012]. The neocortex comprises 80% of the human brain and 72% of the macaque brain, but

only 20% of the rat brain [Hutchison & Everling, 2012; Passingham, 2009]. Importantly, there are functional areas of the primate brain that do not exist in the rat, including visual cortical functional divisions [Uylings et al., 2003] and prefrontal cortex subdivisions [Preuss, 1995; Uylings et al., 2003]. These points are critical for studies of cognitive aging that are focused on cognitive processes dependent upon cortical regions, for example, prefrontal cortex.

Besides similarities in brain functional specialization, NHPs share other vital similarities with humans that distinguish this animal model from rodent species and makes it a significantly unique model for translational investigation of cognitive aging. Humans and NHPs are primarily visually-oriented, unlike rodents. Using NHPs to study cognitive aging allows one the ability to examine visual non-spatial and spatial cognitive processes, thus providing examination of critical cognitive functions relevant to the human conditions being modeled. Considerable translational advantages of using NHPs to study cognitive aging include the shared complexity and breadth of their cognitive abilities with that of humans, especially higher order cognitive functions, for example, the ability to perform numerical operations [e.g., Okuyama et al., 2013]. Using NHPs facilitates the investigation of cognitive aging because it enables the use of established neuropsychological tests that were developed originally to evaluate human cognition to be used to evaluate NHP cognitive abilities [Voytko, 2003] and likewise, the use of experimental paradigms developed originally to evaluate NHP cognition to be used to evaluate human cognition [Voytko, 2003]. For example, the Wisconsin Card Sorting Task (WCST) is the gold standard for assessing cognitive flexibility in humans. Using a version of WCST (without the numerosity category), executive function deficits were noted in middle-age and aged rhesus monkeys [Moore et al., 2003; Moore et al., 2005, 2006] and in menopausal middle-aged rhesus monkeys [Voytko et al., 2009]. The ability to use operationally similar behavioral tasks in both humans and monkeys allows for greater and more reliable extrapolation between these species. Also of important note, identical pieces of equipment and technology can be used interchangeably in cognitive studies of humans and NHPs, for example, computer driven behavioral testing apparatus [Nagahara et al., 2010] and brain radiological equipment and procedures for both imaging [Voytko et al., 2001; Wey et al., 2013] and irradiation [Sundgren & Cao, 2009; Voytko et al., 2012] studies. Besides the already noted unique qualities and aspects of using NHPs to study cognitive aging, female NHPs are the ideal animal models in which to investigate the effects of reproductive aging on both cognitive and brain function. Female NHPs share many reproductive and endocrine features with women; unlike many

common laboratory rodents which have a 4-day estrus cycle and cessation of ovarian function that does not closely resemble primate menopause [Steger & Peluso, 1987]. Of particular note, female macaque monkeys have (1) 28-day menstrual cycles and patterns of ovarian hormones similar to women [Goodman et al., 1977; Jewitt & Dukelow, 1972], (2) a similar menopause to that of women [Downs & Urbanski, 2006; Gilaridi et al., 1997; Johnson & Kapsalis, 1995; Shidler et al., 2001], (3) physiological responses to surgical menopause and estrogen therapy that are similar to women [Adams et al., 1990; Jayo et al., 1998; Jerome et al., 1994], and (4) improvements in cognitive function with estrogen similar to women [Lacreuse, 2006; Rapp et al., 2003; Voytko et al., 2008, 2009]. Moreover, one is able to use novel hormone therapy schedules in NHPs that closely mirror the hormonal fluctuation patterns that occur over the course of a normal primate menstrual cycle [Voytko et al., 2008, 2009]. Thus, female NHPs enable examination of cognitive processes, as well as their modulation by menopause and hormone therapy, that are essentially identical to those found in women.

Although rodents are commonly used for studies of cognitive aging, there are critical neural, reproductive, and endocrine disparities between rodents and primates that likely contribute to the differences in behavioral observations that have been found between NHP and rodent models of aging. Collectively, these factors highlight the continued importance of using NHPs to investigate aspects of human cognitive aging and age-related disease.

DEVELOPMENTAL PROGRAMMING

The Developmental Programming hypothesis states that—*responses to challenges during critical developmental time windows alter development with persistent effects on phenotype*. Extensive human epidemiologic and precisely controlled animal studies show that reduced maternal nutrition, both global calories or protein intake, and other challenges such as maternal obesity and maternal stress during fetal and neonatal development alter the trajectory of organ differentiation and development, predisposing offspring to a wide variety of chronic diseases including cardiovascular disease, obesity, diabetes, and behavioral disorders [Ainge et al., 2011; Armitage et al., 2004, 2005, 2008; Beall et al., 2005; Desai et al., 2005; Fernandez-Twinn & Ozanne, 2010; Li et al., 2011; Morimoto et al., 2011; Papadopoulou et al., 2003; Tosh et al., 2010; Vega et al., 2013; Vickers & Sloboda, 2012; Zambrano et al., 2010].

Controlled experimental studies on developmental programming have almost entirely been conducted in the common polytocous, altricial rodent laboratory species that have a very different developmental trajectory and maternal nutritional load in

pregnancy and lactation compared to relatively precocial, mostly monotocous, species including humans. One central feature of perinatal development in which primates and the common polytocous laboratory animals differ is the interdependence of the fetal and maternal hypothalamo–pituitary–adrenal axis and their interactions with the placenta. One of the most significant differences between precocial and altricial species is the extent to which maternal glucocorticoids can cross the placenta and influence fetal development. Glucocorticoids act as a general orchestrator of late gestational fetal differentiation and maturation playing a central role in the preparations the fetus makes for independent life [Fowden et al., 2006].

The major precocial animal investigated in the field of developmental programming has been the sheep which had great advantages in the ease of accessibility of the fetus, extensive documentation on fetal development and the ability to conduct interventions to determine mechanisms and indicate potential markers in human development [Fowden et al., 2006; Nijland et al., 2008; Tuersunjiang et al., 2013]. However, the sheep has different placentation from primates including humans. Therefore nonhuman primate studies of programming, in ways that allow translation to human development, are needed. To date the major approaches to developmental programming that have been conducted in nonhuman primates have included; global nutrient reduction during pregnancy and lactation in the baboon [Antonow-Schlorke et al., 2011; Cox et al., 2006a, 2006b, 2013; Keenan et al., 2013; Nijland et al., 2010; Tchoukalova et al., 2013]; feeding high fat, high energy diets to Japanese macaque monkeys [Sullivan et al., 2010, 2011] or baboons [Maloyan et al., 2013]; the study of spontaneously growth restricted monkeys [Emerald et al., 2011] and studies on effects of fetal exposure to concentrations of glucocorticoids higher than appropriate for the current stage of gestation as a result of maternal administration of exogenous, synthetic glucocorticoids [Rodriguez et al., 2011]. This last model is of importance because excessive glucocorticoid exposure can produce organs that are both smaller and contain the wrong balance of different cell types.

The central role of glucocorticoids is further indicated by the observation that different challenges to the developing mammal can result in similar outcome phenotypes. Thus a variety of exposures in the perinatal period such as bilateral uterine ligations to mimic intrauterine growth restriction (IUGR) due to disruption of placental blood flow, chronic fetal hypoxia, excess glucocorticoid exposure, environmental insults (tobacco and endocrine-disrupting chemicals), maternal diet restrictions (caloric, iron and protein restriction) and over nutrition (high fat diets and obesity), can result in very similar phenotypes that include obesity, hypertension, insu-

lin resistance, type 2 diabetes and cardiovascular disease in the offspring, suggesting common mechanistic pathways such as exposure to glucocorticoids at higher levels than normal for the current stage of gestation. Several other candidate mechanisms have been proposed that are either dependent on epigenetic mechanisms [Wadhwa et al., 2009; Wang et al., 2012] or oxidative stress [Sen & Simmons, 2010].

The ability to produce experimental models of IUGR is important since IUGR results in much perinatal morbidity and mortality. IUGR occurs not only with poor maternal nutrition but also in maternal obesity especially in primigravidae [Nelson et al., 2010], in teenage pregnancies where the growing mother competes with her fetus for nutrients [Wallace et al., 2006] and in pregnancies associated with placental disease, pre-eclampsia or maternal vascular disease [Roberts & Post, 2008]. Cohorts of male and female baboon offspring of mothers fed either ad lib or 70% of the ad lib global diet in pregnancy and lactation have been developed, resulting in IUGR and reduced growth in early life [Xie et al., 2013]. Three-year-old male IUGR baboon offspring (human equivalent 12 years) show signs of incipient hypertension and metabolic syndrome (MS) [Choi et al., 2011]. Data from nonhuman primate models such as this model and the obese Japanese macaque model studied by investigators at the Oregon Regional Primate Center [Grayson et al., 2006, 2010; Sullivan & Grove, 2010; Suter et al., 2011, 2012] are needed to remove barriers to progress in development of human clinical diagnostic markers, preventative and therapeutic strategies.

An invaluable and powerful practical advantage of studies in both the monkey and baboon is the availability of extensive information on human gene and protein structure that can be extrapolated to these species. Human reagents, such as gene probes and antibodies, generally cross-react in these nonhuman primate species and are available for molecular studies addressing mechanism. For example the normal baboon gene expression phenotype has been extensively characterized at mid- and late-gestation as well as responses to reduced fetal nutrition and IUGR in the placenta [Cox et al., 2013; Li et al., 2009] fetal liver [Li et al., 2009], kidney [Cox et al., 2006a; Nijland et al., 2007] adipose tissue [Tchoukalova et al., 2009] and brain [Antonow-Schlorke et al., 2011] as well as the protein phenotype in liver, frontal cortex of the brain, hypothalamus and kidney. Using these approaches it has been demonstrated that several metabolic pathways are altered in IUGR particularly those involved in mTOR nutrient sensing and the IGF system [McDonald et al., 2007; Nijland et al., 2007; Xie et al., 2013]. In a similar way, studies by another group of investigators noted differential expression of 1,973 genes by microarray between neonates of average or low birth weight.

Gene ontology studies showed changes in several metabolic pathways including carbohydrate metabolism [Emerald et al., 2011]. Alterations that are likely to have persistent epigenetic effects have been described in the Japanese macaque [Suter et al., 2012, 2013].

In summary information of great value in understanding the challenges, exposures, mechanisms and outcomes that lead to developmental programming in humans requires a synthesis of data from common, altricial experimental species as well as precocial nonhuman primates. Much can be learned from the similarities and differences that will be of great value in identifying markers that will enable the choice of preventative interventions and the design of therapies.

GENETICS

The study of nonhuman primates has been and will continue to be a critical aspect of the broader field of genetics and genomics. There are many reasons why investigators study the genetics and genomics of humans and other organisms. Among the major motivations are the desires to understand how genetic variation influences individual differences in risk for or treatment of disease, and the genetic basis of human and primate evolution. Analyses of NHPs contribute much valuable and unique information to these two areas.

A variety of animal species have proven valuable as model organisms for research related to human health and disease. However, recent progress provides numerous examples of specific circumstances in which a fundamental genetic process relevant to a disease can only be modeled in a NHP, that is, where no other species can provide a valid substitute. For example, prostate cancer is a major public health problem causing substantial mortality in the US and other countries. For years, one of the most commonly performed tests to detect cancer has been the prostate-specific antigen (PSA) test, performed to detect prostate cancer early and thus improve treatment outcomes. But the utility of the PSA test has recently been debated, and a more complete understanding of the function and expression of the gene that produces PSA (gene symbol *KLK3*) is important for further research progress. However, the *KLK3* gene occurs only in Old World monkeys, apes and humans, and only these species produce the PSA protein [Karr et al., 1995; Mubiru et al., 2008]. Thus, only primates can be used to investigate the biology of PSA and its correlations with pathology.

A second example of the necessity of primate genetic studies for biomedical research involves psychiatric illness. Anxiety disorders and depression affect millions of people each year, leading to substantial suffering and disability that affects patients, their families, and the wider society.

Susceptibility to anxiety disorders and depression is influenced by various factors, but it is clear that some people inherit a genetic predisposition to these psychiatric problems by virtue of inheriting genetic variation that can reduce their ability to effectively cope with various stressful experiences [Binder & Nemeroff, 2010]. A recent study using the rhesus macaque model investigated variation in the corticotrophin releasing hormone receptor 1 gene (*CRHR1*), which has previously been implicated as exerting significant influence on differences among people in their response to stress [Binder & Nemeroff, 2010; Liu et al., 2006]. This study of macaques identified specific mutations in the *CRHR1* gene that are associated with differences in behavioral responses to mild stress, and also with differences in functional activation of specific neuronal structures (the hippocampus, intra-parietal sulcus and others) in the macaque brain that are in part responsible for the outward expression of anxiety-related behaviors [Rogers et al., 2013]. The hippocampus is well established as a central component of the neural circuitry that underlies emotion and reactivity to stress in humans and other mammals. While the *CRHR1* gene is found in many mammalian species, the specific portion of the gene affected by the newly discovered mutations (exon 6) is a relatively new evolutionary innovation, found in Old World monkeys, apes and humans. Non-primate mammals do not exhibit the same gene structure or protein sequence, and therefore experimental analysis of the influence of these *CRHR1* mutations on neurobiology and risk of psychopathology can only be performed in nonhuman primate models.

Numerous other examples of disease processes that are specific to primates and are significantly influenced by genetic differences among individuals could be described. For example, polycystic ovary syndrome is a common disorder that causes anovulation and infertility in women, is associated with increased risk for obesity and diabetes and is significantly influenced by genetic differences among women [Kosova & Urbanek, 2013]. This disorder is also well documented in rhesus macaques but cannot be adequately modeled in non-primate species [Abbott et al., 2013]. Primates are also uniquely suited to modeling the influence of genetics on immunobiology and risk for infectious disease. Susceptibility to infection by HIV and subsequent progression to AIDS is significantly affected by genetic differences among people [Guergon & Theodorou, 2011]. Rhesus macaques are the premier animal model for studying HIV/AIDS, and macaques also exhibit individual differences in response to infection by SIV [Loffredo et al., 2007]. Only these NHP can be used to investigate the genetic basis of individual variation among hosts in response to challenge with SIV and related viruses. In other cases, especially circumstances related to

neurobiology and immunology, particular disease processes depend on genetic mechanisms that are shared between humans and NHPs, but not with other species [Barr et al., 2003; Lesch et al., 1997; Seok et al., 2013a].

One aspect of comparative biology that fascinates both scientists and the general public is the question of human origins. What are the genetic differences that account for uniquely human characteristics including our expanded brain, increased cognitive complexity, extended lifespan, spoken language, bipedal locomotion and others? It is obvious that efforts to identify the particular genetic changes underlying unique human traits must compare the content and function of the human genome with that of closely related species. Comparative analyses of the human, chimpanzee, gorilla, and orangutan genomes are beginning to identify specific DNA sequence changes that seem to account in part for specific aspects of human evolution [Charrier et al., 2012; O'Bleness et al., 2012; Prabhakar et al., 2008], but much more research is needed. In addition, comparisons across a wider set of primates, including Old World monkeys, New World monkeys, and strepsirrhines are essential for development of a comprehensive understanding of how our hominoid relatives (chimpanzees, gorillas, orangutans and gibbons) arose out of more primitive non-hominoid ancestors. Only through detailed analysis and comparison of multiple primate genomes will we reconstruct the history and processes of genetic change that produced our species and our close relatives. This research also generates information about the genetic basis of more widely shared fundamental aspects of primate biology, thus increasing our knowledge of basic biology and evolution [Jolly et al., 2011; Prado-Martinez et al., 2013; Roos et al., 2011; Zinner et al., 2013].

HIV/AIDS

Human immunodeficiency virus (HIV), the etiologic agent of AIDS, evolved as a result of cross-species transmissions of simian immunodeficiency viruses (SIV) from African NHP species [Gao et al., 1999; Sharp & Hahn, 2011]. Although HIV infection is endemic in human populations, its host range is highly restricted. Only a handful of great ape species are susceptible to HIV infection [Alter et al., 1984] and AIDS-like diseases have only been observed in sporadic cases of experimentally infected chimpanzees [O'Neil et al., 2000]. As such, there is currently no experimental animal model that can capture the full spectrum of HIV infection in humans and its clinical sequelae. Despite this obstacle, substantial progress in HIV/AIDS research has been made in the past two decades with "surrogate" models such as SIV infection of macaques [Evans & Silvestri, 2013; Lifson & Haigwood, 2012; Van Rompay, 2012; Veazey, 2013].

SIV was first isolated in 1985 from rhesus macaques that presented with AIDS-like conditions, including CD4⁺ T cell depletion, opportunistic infection and neoplastic diseases [Daniel et al., 1985]. This virus was later found to be closely related to a primate lentivirus (SIVsm) endemic in populations of sooty mangabeys in Africa [Hirsch & Johnson, 1992]. Although SIVsm infection in their natural hosts is generally non-pathogenic, experimental inoculation of Asian macaques can result in AIDS-like diseases [Apetrei et al., 2005]. Because of its ability to induce AIDS-like diseases in relatively accessible NHP species, infection of macaques with SIVsm and its derivatives (e.g., SIVmac, SIVsmm, SIVmne, etc.) has been the animal model of choice for HIV/AIDS research.

SIVsm is believed to have evolved from a common ancestor with HIV type 2 (HIV-2), with which it shares similar virion structures, genomic organization, cellular tropism, and replication strategies [Hirsch et al., 1989]. However, SIVsm is only distantly related to HIV-1 (~40% genetic homology with HIV-1, vs. ~80% with HIV-2). Significant differences exist in their coreceptor usage, accessory genes, and sensitivity to host restriction factors and antiviral drugs [Hatzioannou et al., 2009]. Because of these differences and because HIV-1 does not readily establish infection in macaques, chimeric viruses have been developed, in which specific HIV-1 genes (e.g., *envelope*, *Env*; or *reverse transcriptase*, *RT*) [Ambrose et al., 2007; Hatzioannou et al., 2009; Shibata et al., 1997; Uberla et al., 1995] were inserted into the genome of a pathogenic SIV clone, SIVmac239. Inoculation of macaques with these SHIV chimera resulted in persistent infection, and, usually after serial in vivo passages, rapid CD4⁺ T-cell depletion and AIDS-like diseases. SHIV shares many of the advantages of SIV/macaque models, but also allows direct testing of specific HIV-1 vaccines (e.g., HIV-1 Env-based vaccines), or antiviral drugs (e.g., some HIV-1 RT inhibitors).

The primary advantage offered by the NHP model is the opportunity it affords to control the experimental conditions of infection and to collect tissues, especially those at early stages of infection, that are otherwise difficult or impossible to obtain from humans. Thus, NHP studies have been instrumental in shaping our understanding of the pathogenic mechanism of primate lentivirus infection in general and the early events after transmission in particular. The NHP model has also been an important tool for proof-of-concept studies of novel therapeutic and prophylactic approaches against HIV infection and disease [Clements et al., 2011; Del Prete & Lifson, 2013; Garcia-Lerma & Heneine, 2012; Lifson & Haigwood, 2012; Van Rompay, 2012; Veazey, 2013]. Summarized below are a few examples of how NHP models have contributed to the field of AIDS research.

Because of the ability to control experimental conditions, such as the timing, the route and the composition of the virus inoculum, the NHP model has played an important role in informing us of the early events in lentivirus transmission [Haase, 2011]. For example, intrarectal or intravaginal inoculation of macaques with low dose SIV have shown that infection through mucosa is often initiated with only a small number of “transmitted/founder” viruses, similar to the “bottleneck” observed in sexual transmission of HIV in humans [Keele et al., 2009; Shaw & Hunter, 2012]. In 1996, Marx et al. [1996] reported progesterone implants enhanced mucosal transmission of SIV in macaques, most likely due to the thinning of vaginal mucosa resulting from the hormone treatment. Similarly, subsequent clinical trials indicated that injectable contraceptives may be a risk factor for HIV-1 transmission through direct effects on genital mucosal HIV-1 replication [Heffron et al., 2012]. NHP models therefore offer a highly relevant experimental platform to study factors that influence HIV transmission and to evaluate approaches to prevent acquisition.

NHP models have also provided important insights on the pathogenic mechanism of HIV infection. Studies of early events after SIV infection of macaques helped identify central memory CD4+ T cells (T_{cm}) and gut-associated lymphoid tissues (GALT) as the primary targets of infection [Heise et al., 1994; Mattapallil et al., 2005; Veazey et al., 1998]. The rapid and early depletion of T_{cm} in GALT, coupled with the dysregulation of homeostatic signals and the destruction of the gut mucosa, results in microbial translocation, inflammatory responses, activation of target cells and enhanced viral replication. These cyclical events set in motion an irreversible loss of gut T_{cm} and ultimately the collapse of the immune system. Similar observations made in clinical studies and NHP models [Brenchley et al., 2004, 2007; Klatt et al., 2010; Mehandru et al., 2004] inform our current understanding of the pathogenic mechanism of HIV infection and point to potential novel therapeutic approaches [Klatt et al., 2013].

NHP models played an important role in the development of prophylactic treatment concepts and topical microbicides against HIV acquisition. Using an SIV model, Tsai et al. [1995] and colleagues protected macaques against SIV infection and disease by treatment with an antiviral drug pre- or post-exposure. They further showed that the timing of the initiation and duration of treatment was critical [Tsai et al., 1998]. These early proof-of-concept studies in NHP models predicted the success of prophylactic use of antiviral drugs [Grant et al., 2010; Van Damme et al., 2008] and provided much of the basis for the development of post-exposure prophylaxis as a treatment regimen in the clinic [Grant, 2010].

Studies in NHP models also predicted the efficacy of topical microbicide to reduce vaginal transmission of HIV [Abdool Karim et al., 2010; Dobard et al., 2012; Veazey, 2013]. Despite controversies over the discrepancy between findings from NHP models and early clinical trials, recent studies have shown that, if the studies were designed and interpreted properly, results from NHP models are highly predictive of the clinical outcomes. For instance, nonoxynol-9, a non-specific antiviral compound, was shown to be efficacious in vitro and in animal models [Hillier et al., 2005]. However, studies in the clinic showed increased HIV acquisition with the use of nonoxynol-9, most likely due to the inflammatory responses it causes in the vaginal/cervical mucosa [Hillier et al., 2005; Van Damme et al., 2008]. This result cast significant doubt on the value of NHP models in general. However, when repeated nonoxynol-9 dosing in the clinical trial was modeled in macaques, similar findings of inflammatory responses in the vaginal/cervical mucosa were observed [Van Rompay, 2012; Veazey, 2013]. Thus, proper interpretation of results from animal models requires considerations not only of the intrinsic differences between experimental systems, but also the comparability of the trial designs.

Natural history studies of HIV exposed individuals do not support the notion that protective immunity against HIV infection and diseases can be acquired through natural exposure, as has been demonstrated in many vaccine-preventable diseases. Until the report of the RV144 trial in 2009 [Rerks-Ngarm et al., 2009], the only direct evidence supporting the feasibility of vaccine induced protection against primate lentivirus infection and disease was provided by NHP models. Since the late 1980's, a number of vaccine concept and immunization approaches have been shown to induce different levels of protective immunity against primate lentiviruses in a variety of NHP models. Live attenuated vaccine, long considered as the “gold standard” vaccine approach against viral diseases, was shown to be effective against SIV_{mac} infection [Daniel et al., 1992]. However, this live attenuated vaccine was subsequently shown to induce AIDS in infant macaques, demonstrating the usefulness of the NHP model to address safety concern of this vaccine approach [Baba et al., 1995, 1999]. Protective efficacy of the “prime-boost” strategy, using poxvirus for priming and subunit protein for boosting, was also first demonstrated in a NHP model in 1992 [Hu et al., 1992]. Seventeen years later, a similar strategy, using canarypox viruses and subunit gp120 proteins in a “prime-boost” regimen, provided the first indication that vaccine protection against HIV acquisition is possible [Rerks-Ngarm et al., 2009]. Although the efficacy of this vaccine regimen still needs to be confirmed, understood and improved upon, a number of “prime-boost” immunization approaches, using various replicative or non-replicative vectors (including DNA) and different

boosting immunogens, are being developed and evaluated in the clinic. More recently, Picker and colleagues [Hansen et al., 2011, 2013], using a NHP model, showed that significant protection and durable antiviral immunity can be achieved by a cytomegalovirus (CMV) vector based vaccine.

Despite its limitation as a surrogate model, NHP represents the most relevant animal model for HIV/AIDS research to date. Studies in NHP models have contributed much to our understanding of the early events of HIV infection and its pathogenic mechanisms. NHP have also been proven useful in the development of therapeutic and prophylactic treatment concepts and microbicides. Better understanding and judicious use of NHP models will continue to inform HIV vaccine development and the search for a cure for AIDS.

IMMUNOLOGY

The immune system has a central regulatory role in the maintenance of homeostasis within the body and is involved in almost all aspects of human health and disease. Outside the usual suspect disorders—*infection, asthma/allergy, autoimmunity, and transplant rejection*—the immune system has a role in neurodegenerative diseases (Alzheimer, Parkinsonism) and even in psychiatric diseases (schizophrenia) and mood disorders (depression).

According to the classical dogma, the immune system learns during fetal development to respond only against non-self (e.g., foreign agents or a transplanted organ) but not against self, that is, it tolerates its own body. However, more recent insights show that the distinction made by the immune system is between real threats (danger) against which an immediate response is required and relatively harmless disturbances of homeostasis, which can be ignored [Matzinger, 2002]. The immune system perceives danger via innate receptors expressed on the surface of professional antigen presenting cells (APC)—dendritic cells and macrophages, for example—which detect conserved molecular structures on pathogens, such as bacterial lipopolysaccharide or viral RNA [Mills, 2011]. The detection of danger induces activation of the APC whereby they acquire the capacity to mobilize effector T and B lymphocytes and tailor their response [Iwasaki & Medzhitov, 2010]. This innate part of the immune system is present throughout the animal kingdom. Information on encountered pathogens is stored within the adaptive part of the immune system, which is only present in vertebrate species. The adaptive system comprises T and B cell lymphocytes, which store immunological memory via expansion of the responding clonal specificities and molecular imprinting, ensuring a quicker and more effective reaction upon re-encounter of the pathogen.

Many of our current concepts on the architecture and functioning of the human immune system comes

from well-characterized inbred and specific pathogen-free mouse strains. Although the blueprint of the mouse innate and adaptive immune system is representative for the human system, translation of immunological principles from laboratory mice to humans has been notoriously difficult. This is in part explained by basic immunological differences between mice and humans [Mestas & Hughes, 2004], but it is also due to the immunological immaturity of the very clean (SPF) laboratory mouse [Sachs, 2003]. The direct consequence of immaturity is that the mouse immune system is much more amenable to experimental manipulation than the robust, pathogen-educated immune system of humans [Sachs, 2003].

Although as many as 11 ground-breaking immunological discoveries have been awarded with a Nobel prize, making immunology one of the most successful disciplines in medicine and physiology, rather few discoveries in basic immunology could be incorporated in clinical practice. Indeed, we have now effective vaccines against some infectious diseases, we have monoclonal antibodies for diagnosis and treatment of autoimmune diseases and cancer, and we can successfully replace certain dysfunctional body organs (skin, heart, kidney, liver, lung) and tissues (bone marrow). However, these evident successes are contrasted by a long list of new treatments for immune-mediated inflammatory disorders that fail to reproduce beneficial effects observed in mouse models when they were tested in the clinic. Not only are the investment losses due to the high attrition rates enormous [Kola & Landis, 2004], but it also shows how little we understand of the human immune system [Davis, 2008].

Obstacles to the translation of pathogenic and therapeutic principles from mouse to man are in part related to the artificial nature of the disease models, which often do not replicate the essence of the human disease, but certainly also to the considerable immunological gap between a clean laboratory mouse and humans. Another bias is the short life span of a laboratory mouse that makes it a less suitable model for diseases associated with aging. Despite these obvious limitations, the inbred/SPF laboratory mouse is the standard experimental model for the vast majority of immunologists in academia and industry. Frequently heard arguments in support are the abundance of reagents, availability of well-characterized genetically modified animals, the relatively low costs, the reliability of the models implying high reproducibility of experiments, and the fact that the standard disease models are accepted in the field implying easier acceptance by reviewers and editors of the leading journals [Steinman & Mellman, 2004].

Nonetheless, the notion that a nonhuman primate may be the more relevant model for human biology and disease—due to their closer genetic, immunological and anatomical proximity to humans

and the fact that their housing in outdoor enclosures allows exposure to immune shaping environmental cues—is (slowly) gaining acceptance. In the field of transplantation, the nonhuman primate is an inevitable model for proving the efficacy of a new treatment before it can be tested in the clinic [Sachs, 2003]. It is difficult to understand why the same argumentation would not be applicable to the autoimmune disease field, where the nonhuman primate is much less accepted as a relevant preclinical model. However, efforts to develop the experimental autoimmune encephalomyelitis (EAE) model in common marmosets, as a generic autoimmune disease model for exploratory research into etiopathogenic mechanisms and applied research into novel therapies for multiple sclerosis, seem to be bearing fruit [t Hart et al., 2011].

NEUROSCIENCE

NHPs provide important models for neuroscience research for a variety of reasons. Chief among these is the similarity with humans in both central and peripheral nervous system structure and organization. Compared to other mammals, such as rodents, nonhuman primates' brains resemble human brains most closely on a variety of criteria including encephalization (a measure of brain size relative to a taxonomic standard), number and density of cortical neurons, a large prefrontal cortex, and greater myelination [Roth & Dicke, 2005; Semendeferi et al., 2002; Ventura-Antunes et al., 2013]. For example, the encephalization quotient for humans is 7.4–7.8. For Old World monkeys, the values range from 1.7 to 2.7, and for capuchin monkeys, the values range from 2.4 to 4.8. In contrast, encephalization quotients for rats and mice are in the 0.4–0.5 range [Roth & Dicke, 2005]. Important cytoarchitectural differences between primate and rodent brains have also been reported in areas associated with adult neurogenesis [Brus et al., 2013], and particular structural and functional areas, such as the frontal and temporal poles, appear to be unique to primates [Insausti, 2013; Tsujimoto et al., 2011]. Differences between rodents and primates exist in spinal cord anatomy as well [Courtine et al., 2007].

Humans and Old World monkeys (which are most commonly used as model species in neuroscience research) also share important aspects of their lifestyles (e.g., diurnality, terrestriality, omnivory), sensory/perceptual abilities (e.g., color vision, greater reliance on vision than olfaction), anatomical specializations (e.g., use of hands and thumbs, rather than vibrissae, for tactile perception), and genetics. The similarities between human and NHPs in these features are reflected in brain organization. For example, comparative studies of a variety of mammalian taxa have shown that all species possess primary and secondary sensory areas [Krubitzer,

2007]. The internal organization of these areas, however, can reflect broader anatomical differences, with a relatively higher proportion of primary somatosensory cortex devoted to the hand in primates, compared to a high proportion devoted to the vibrissae in rats [e.g., Seelke et al., 2012]. Because of anatomical similarities and specializations, nonhuman primates are important subjects in the emerging field of neuroprosthetics [O'Doherty et al., 2011], which may eventually result in an exoskeleton that could restore mobility to paralyzed humans. Considerable research is ongoing with nonhuman primates in the areas of sensory neuroscience, focusing on basic questions of how color is processed in the cortex [Hass & Horwitz, 2013], and what neurological mechanisms are associated with age-related hearing loss [Engle et al., 2013]. Advances in genetics have likewise shown associations between genetic polymorphisms that are much more conserved in anthropoid primates than among mammals in general (such as those coding for the corticotropin-releasing hormone receptor 1), and metabolic activity that is relevant to understanding brain mechanisms associated with anxious temperament [Rogers et al., 2013].

Similarity in aspects of life-history also makes NHPs valuable models. Year-round sociality, relatively long gestations, singleton births, the lengthy period of postnatal development, long lifespan, and for some species, the development and persistence of adult pair bonds, permit questions to be asked about the neuropeptide basis of monogamy [Jarcho et al., 2011], the role of early experience in the development of brain systems subserving affiliation [Winslow et al., 2003], and the importance of the social environment in affecting sympathetic nervous system innervation of lymphoid tissue [Sloan et al., 2007].

NHP models are also making significant contributions in the understanding and treatment of diseases and injuries that affect large numbers of humans, including Alzheimer's Disease, Parkinson's Disease, and NeuroAids [Capitanio & Emborg, 2008]. Some of these studies have led to clinical trials [e.g., Tuszynski, 2007]. New models continue to be developed (e.g., Huntington's Disease [Yang et al., 2008]), and thoughtful discussion about the development of valid nonhuman primate models for pathological neurological conditions and treatments is ongoing [e.g., Cook & Tymianski, 2012; Kimmelman et al., 2009]. Advances in imaging technologies, including diffusion spectrum imaging and resting-state functional magnetic resonance imaging [e.g., Koo et al., 2013; Kroenke, 2010] and references therein), enable study of human and nonhuman primates using the same methodologies. Importantly, however, the greater access to the brains of nonhuman primates permits validation of the imaging data through comparison with data obtained from more invasive measures, and provides a level of resolution

(e.g., down to the single cell level) that is still unobtainable via neuroimaging with humans [Passingham, 2009].

PHARMACOLOGY

As discussed above, NHP social behavior can serve as a dependent variable in examining the effects of neuropathology associated with human psychiatric diseases and the drugs used to treat them. In addition, the position in the social hierarchy that is occupied by a monkey can serve as an independent variable. That is, the social rank of a monkey can affect physiology, behavior and the effects of drugs. In the wild and when housed in groups in captivity, monkeys establish clear dominance hierarchies. In the laboratory setting, which often involves relatively small groups, these hierarchies are linear and transitive. Occupying the lower, subordinate positions in the hierarchy is unequivocally stressful. Compared to dominant monkeys, subordinates display suppressed ovarian function, heavier adrenal glands and greater release of cortisol in response to stressors, which indicated a hyper-sensitive HPA axis [e.g., Czoty et al., 2009; Kaplan et al., 1986; Shively & Kaplan, 1984]. Whereas subordinates are exposed to chronic social stress, dominant monkeys live in a chronically enriched environment. Top-ranked monkeys move about the pen as they please, receive more grooming and have primary access to food and other resources. Importantly, position in the social hierarchy can influence the brain as well as effects of drugs. Thus, socially housed NHPs represent an excellent example of the ability of environmental factors to influence drug effects.

One research area in which such drug \times environment interactions have been extensively documented is the study of the effects of abused drugs [Nader et al., 2012]. For example, Miczek and collaborators have shown that the behavioral effects of *d*-amphetamine and alcohol differ in dominant and subordinate monkeys [e.g., Miczek & Gold 1983; Winslow & Miczek, 1985]. In dominant but not subordinate cynomolgus monkeys (*Macaca fascicularis*), the transition from individual to social housing was associated with an increase in the binding availability of D2/D3 dopamine receptors, as measured with positron emission tomography (PET imaging), and lower sensitivity to the abuse-related effects of cocaine [Morgan et al., 2002]. Although several years of cocaine self-administration experience resulted in a dissipation of this social rank-related difference, the significant difference re-emerged once cocaine exposure was discontinued [Czoty et al., 2004, 2010]. Because brain dopamine and D2/D3 receptors in particular have been strongly linked to the behavioral effects of cocaine [e.g., Koob & Volkow, 2010], these studies provide a clue to the mechanisms that underlie the ability of the environment to modulate

the behavioral effects of drugs. Although rodents will establish dominance hierarchies in the laboratory under some conditions [e.g., Blanchard & Sakai, 1993], the vast majority of rodent research uses individually or pair-housed animals. NHPs afford the opportunity to study ethologically relevant sources of environmental stress and enrichment over long periods of time.

Whereas the sophisticated social and behavioral repertoire of monkeys proves advantageous for studying complicated interactions between the environment, the brain and behavior, NHPs have advantages as subjects in more direct pharmacological studies as well. Beyond the closeness between monkeys and humans in phylogeny, neuroanatomy and neurochemistry, it is also apparent that monkeys are the most predictive animal model of the pharmacokinetics of various drugs [see Weerts et al., 2007]. Furthermore, human drug addicts typically abuse multiple substances over a period of several years before seeking treatment. It is questionable whether a few days or weeks of drug exposure in laboratory animal adequately models the complex pharmacological history observed in humans. Only in species with a lifespan as long as monkeys is it possible to generate subjects with long and varied pharmacological histories. For example, Nader et al. (2006) used PET imaging to study brain changes in monkeys self-administering cocaine for 1 year. A progressive decrease in the binding availability of D2/D3 receptors was observed in all monkeys, but the time course of this effect differed. Had the analysis terminated after one week or even one month of cocaine self-administration, it would have appeared that only some monkeys were affected. Moreover, when access to cocaine was removed, the time course and extent of recovery of D2/D3 receptor availability to baseline levels also differed across subjects. Thus, monkeys are ideal research subjects not only for the ability to track changes in the brain and sensitivity to drugs over time, but also to be able to study individual differences in these effects—both of which are omnipresent in clinical medicine (see reviews by Gould et al., 2012, 2013; Howell & Murnane, 2011; Murnane & Howell, 2011; Nader & Banks, 2014).

REPRODUCTION

Despite many basic similarities in the endocrine regulation of reproduction that are common among mammals [Ferin, 1983; Karsch et al., 1984; Plant & Witchel, 2006], primates exhibit characteristics not common among other taxa [Weinbauer et al., 2008] and historically have been valuable in elucidating reproductive biology of specific relevance to humans [Dettmer, 2013]. For instance, negative feedback by estradiol inhibits the release of luteinizing hormone (LH) more potently in female than male primates and rodents [Steiner et al., 1976]. In contrast, the sexually

differentiated positive feedback effect of high estradiol, that induces an LH surge in female but not male rats [Neill, 1972; Neill et al., 1971], is not sexually differentiated in primates [Karsch et al., 1973], and estradiol can elicit surge release of LH in both males and females [Steiner et al., 1976]. The effects of administered neuropeptides may also differ between species. GnRH can induce testicular damage in rats but not monkeys [Weinbauer & Nieschlag, 1989].

There are fundamental differences in the sources of sex steroids in primates compared with other mammals. The major source of circulating androgens in higher primates is the adrenal cortex [Conley et al., 2004; Nguyen & Conley, 2008], and higher primates experience a pre-pubertal increase in adrenal androgen secretion (adrenarche), the regulation of which is similar in many ways to the human phenomenon [Conley et al., 2012]. Ovarian steroid secretion during the non-pregnant cycle is also notably different in primates from that in most other mammals. It has been known for some time that, uniquely perhaps among higher species, the primate corpus luteum expresses, in addition to progesterone, high levels of aromatase [Doody et al., 1990], and secretes estradiol in concentrations that are measurable in serum [Bosu et al., 1972, 1973], as well as in urine [Hopper & Tullner, 1970]. Secretion of estradiol during the luteal phase maintains vaginal cornification in primates at levels not vastly different from those seen in the follicular phase before ovulation [Patton et al., 2000]; there is far less cyclic change than is seen in rodents [Eckstein & Zuckerman, 1956]. As a result, the vaginal epithelium remains thick, ensuring protection against infection and trauma during copulation throughout all stages of the cycle. This is an important physiological adaptation because many higher primates [Dixson, 1998], unlike most mammals, engage in copulation throughout their reproductive cycle.

Similarly, uterine physiology differs in primates, experiencing events that are uncommon among other mammalian taxa, if not unique. Primates menstruate [Butler, 1974], and only certain chiropteran species share this phenomenon to any similar degree [Rasweiler IV & Badwaik, 2000]. Menstruation in higher primates follows luteolysis in non-conceptive cycles [Brenner & Slayden, 2012; Jabbour et al., 2006]. Luteolysis in primates occurs by mechanisms independent of the uterus as in women [Davis & Rueda, 2002]. Rodents have spontaneous ovulation, but an induced luteal phase and do not experience luteolysis under normal circumstances [Melampy & Anderson, 1968]. If pregnancy is established in primates, luteal function is rescued by the embryonic secretion of chorionic gonadotropin [Banerjee & Fazleabas, 2010; Hearn, 1986]. Equine species are the only other mammals that are known to secrete a chorionic gonadotropin, although secretion is initiated at a much later stage in pregnancy, and therefore

the functional significance differs from that of primates [Allen & Stewart, 2001].

Pregnancy in primates is associated with quite variable profiles of estrogens and progesterone. Even though no two mammals of any species are exactly alike [Conley et al., 2004], estrogen secretion is still dependent on fetal adrenal androgens [Mapes et al., 2002] among the majority of primate species investigated [Conley et al., 2004; Nguyen & Conley, 2008]. This is again unusual among mammals and provides unique insights into possible mechanisms [Pattison et al., 2007]. Furthermore, progesterone remains elevated until parturition in primates [Casey & MacDonald, 1997; Challis et al., 2000; MacDonald et al., 1982; Mendelson, 2009] unlike many other mammalian species. Human birth occurs predominantly at night [Jolly, 1972], and melatonin likely plays a prominent role in both maternal and fetal compartments during pregnancy [Tamura et al., 2008]. In fact, maternal hormone secretion patterns have a distinct diurnal rhythm that correlates with myometrial activity [Wilson et al., 1991]. Consequently, non-human primates are very valuable models for studies into the initiation of labor and preterm birth [Challis et al., 2000; Nathanielsz, 1998]. They have proven equally valuable in studies of fetal development, placental function [Albrecht & Pepe, 1990] and the post-natal effects of in utero hormonal exposure [Abbott et al., 2008]. Mammary development and lactational physiology does not exhibit features that could be considered unique to primates, but NHP physiology and development will always resemble that of humans more closely than non-primate species. As expected therefore, morphological development [Wood et al., 2007a], differentiation [Stute et al., 2012], response to exogenous hormones and development of disease [Cline, 2007; Wood et al., 2007b] are more similar to the human than other traditional model species. Moreover, recent studies suggest that this is reflected even in the mammary epithelial transcriptome [Lemay et al., 2013] and metabolome [O'Sullivan et al., 2013]. Consequently, NHP may also prove to be more valuable and appropriate models to address critical questions in mammary gland disease, lactation, and neonatal nutrition [Neville et al., 2012].

The rhesus macaque has long been recognized to be a good model of human menopause [Hodgen et al., 1977; Johnson & Kapsalis, 1998; Walker, 1995; Walker & Herndon, 2008]. As in women, the perimenopause in macaques is characterized by an increase in FSH [Downs & Urbanski, 2006; Hodgen et al., 1977; Kavanagh et al., 2005; Shideler et al., 2001] and LH [Hodgen et al., 1977; Walker, 1995; Woller et al., 2002] and decreasing inhibin [Downs & Urbanski, 2006; Shideler et al., 2001] as follicle reserve declines [Nichols et al., 2005]. This appears true of other primates [Jones et al., 2007; Walker

et al., 2009], even if cycles continue [Lacreuse et al., 2008]. Although gonadotropins are elevated in perimenopausal rhesus females, estradiol may not be decreased significantly [Walker, 1995], and in longitudinal studies were numerically (145%) higher [Downs & Urbanski, 2006]. As in women [Burger et al., 2002], estradiol concentrations and cycle length becomes irregular [Downs & Urbanski, 2006; Gilardi et al., 1997; Gore et al., 2004; Hodgen et al., 1977; Shideler et al., 2001] with extended follicular phases [Gilardi et al., 1997]. Eventually there is complete ovarian senescence with low estradiol [Gilardi et al., 1997; Gore et al., 2004; Hodgen et al., 1977]. GnRH pulses [Gore et al., 2004] are elevated in aged female rhesus, as are transcripts for GnRH, KiSS-1 and its receptor in medial basal hypothalamus [Kim et al., 2009]. Like women [Crawford et al., 2009; Lasley et al., 2002], cross-sectional data from a small number of subjects suggests that peri-menopausal rhesus may also have variably elevated DHEAS concentrations [Shideler et al., 2001]. Aged rhesus females suffer cognitive deficits [Roberts et al., 1997] that respond to estradiol therapy [Rapp et al., 2003] as do women [Paganini-Hill & Henderson, 1996] (see Cognitive Aging section). In summary, primate reproduction is regulated in ways that are fundamentally different from rodent and other mammalian species, making it imperative to use primate models when investigating reproductive development and associated diseases.

RESPIRATORY DISEASES

According to the American Lung Association, more than 25 million Americans are living with a chronic lung disease such as chronic obstructive pulmonary disease (COPD) or asthma. In 2010, COPD alone was the fourth most common cause of premature mortality in the United States, resulting in over 150,000 deaths [Collaborators et al., 2013]. According to the Centers for Disease Control and Prevention, 10% of children under the age of 18 in the United States have asthma. Given these statistics, it is imperative for the scientific community to study both the initiating events and subsequent intervention of chronic lung disease throughout the lifespan. Despite these efforts, years of life lost due to premature mortality by lung cancer and chronic obstructive disease death are increasing, whereas rates of death from other common causes such as ischemic heart disease, and stroke are declining [Collaborators et al., 2013]. Translational research is hampered not only by limited funding, but also disappointing drug trials that have not led to interventions or have demonstrated considerable side effects. Although controversial, it has been speculated that the limited success of compounds such as those selected to treat asthma is due to the original observations collected from genetically mod-

ified mice, which are currently the most prevalent laboratory animal model used to study human lung disease [Wenzel & Holgate, 2006]. While we have obtained a significant amount of information regarding immunological mechanisms from the rodent, it remains unclear how relevant such findings are to human subjects [Seok et al., 2013b].

Chronic lung disease in both adult and pediatric patients is highly complex, often an interaction of immunity gone awry and alterations in the structure of the lung. Ultimately, a secondary model system that can effectively be used to recapitulate human disease must accurately reflect cellular form and function for both immune and pulmonary compartments. Of all laboratory animals, the nonhuman primate is most similar to humans with regard to developmental maturation of the immune system. For example, thymectomy of neonatal mice results in the development of autoimmune disease, indicating that T cell selection (self vs. non-self; see Immunology section) is not complete at birth, and could potentially become modulated by environmental exposures [Suri-Payer et al., 1999]. In contrast, thymectomy of human infants results in no adverse clinical outcomes, indicating that selection of the T cell repertoire is mostly complete at birth [Wells et al., 1998]. Comparative studies in the infant rhesus macaque suggest that postnatal development of systemic immunity closely parallels that which is observed in human infants [DeMaria et al., 2000]. There are also important similarities in lung development between human and nonhuman primates that are not found in rodents. Humans and other primates share a mixture of cell phenotypes within the conducting airways not found in non-primate species [Plopper et al., 1992]. The overall pattern of conducting airway epithelial differentiation [Jeffery & Reid, 1977; Plopper et al., 1986] and its maturation during the postnatal period are also similar in rhesus monkeys and humans [Bucher & Reid, 1961; Plopper et al., 1986; Thurlbeck et al., 1961]. Collectively, the nonhuman primate exhibits features of lung architecture and immunity that make it highly appropriate for elucidating novel therapeutic approaches to treat chronic lung disease in humans [Plopper & Hyde, 2008].

What have nonhuman primates taught us about chronic lung disease in humans? One important characteristic of normal lung growth in children is that alveolar growth is continuous from birth through school age, a finding that was originally reported in a limited number of postmortem samples [reviewed in Burri, 2006]. Yet, when Hyde and colleagues evaluated rhesus macaque monkeys, the trajectory of alveolar growth was found to be continuous through early adulthood; this observation has significant implications with regards to prolonged susceptibility of younger individuals to lung damage from environmental pollutants [Hyde et al., 2007]. Indeed, studies over 20 years ago in bonnet and rhesus monkeys have

provided compelling histological data on the destructive nature of ambient air pollutants such as ozone on the conducting airways, and lent critical scientific support to establishment of National Ambient Air Quality Standards by the Environmental Protection Agency [Harkema et al., 1993; Mellick et al., 1977]. While all age groups are susceptible to the inflammatory effects of environmental air pollutants, epidemiology suggests that young children are more vulnerable to detrimental long-term health outcomes such as asthma. Because it is considered unethical to conduct experimental trials in healthy pediatric subjects, studies have relied on infant rhesus monkeys to provide data on long term health effects of environmental exposures such as ozone, tobacco smoke, and allergens. For example, perinatal environmental tobacco smoke exposure in infant monkeys results in altered immune cytokine profiles and airway innervation [Yu et al., 2008]. The health effects of environmental exposures can persist long after the exposure has ended, as evidenced in a study by Maniar-Hew et al. [2011], in which early life ozone exposures resulted in attenuation of innate immune responses in mature monkeys. Nonhuman primate models of allergic airways disease have been in existence for over 40 years, exploiting both a naturally occurring parasitic infection in the wild (*Ascaris spp.*) as well as experimental sensitization with the common human allergen, house dust mite [reviewed in Coffman & Hessel, 2005]. While both ascaris and house dust mite monkey models have been used to test a number of compounds over the past 5 years, including an anti-IL-13 inhibitor and an inhibitor of OX40L [Bree et al., 2007; Seshasayee et al., 2007], a NHP study of steroid use in childhood asthma has provided important data on the disruptive impact on lung development of this common therapeutic [Plopper et al., 2012]. Overall, what we have learned from the nonhuman primate has had a significant impact on our understanding of the origins and treatment of chronic lung disease in multiple age groups, but it is clear that there is still much more work to be completed before chronic lung disease can be prevented or cured.

CONCLUSION

NHPs provide highly valuable animal models that have significantly advanced our understanding of numerous behavioral and biological phenomena in humans and other primates. Their value as models of human biological and behavioral processes derives from their common ancestry, and is evident in the unique characteristics that they possess in comparison to non-primate mammals. However, we are at a critical crossroads. Unless NHP research is given the philosophical, emotional, and financial support and infrastructure that is needed to sustain it and grow, we are in danger of losing irreplaceable unique

models and thus, our ability to continue to explore and understand, and develop preventions and treatments for numerous conditions that inflict great suffering on humans.
